Large-scale arrays of single- and few-layer MoS₂ nanomechanical resonators

Hao Jia, Rui Yang, Ariana E. Nguyen, Sahar Naghibi Alvillar, Thomas Empante, Ludwig Bartels and Philip X.-L. Feng

We report the fabrication of large-scale arrays of suspended molybdenum disulfide (MoS₂) atomic layers, as two-dimensional (2D) MoS₂ nanomechanical resonators. We employ a water-assisted lift-off process to release chemical vapor deposited (CVD) MoS₂ atomic layers from a donor substrate, followed by an all-dry transfer onto microtrench arrays. The resultant large arrays of suspended single- and few-layer MoS₂ drumhead resonators (0.5–2 μm in diameter) offer fundamental resonances ($f_0$) in the very high frequency (VHF) band (up to ~120 MHz) and excellent figures-of-merit up to $f_0 \times Q \approx 3 \times 10^{10}$ Hz. A stretched circular diaphragm model allows us to estimate low pre-tension levels of typically ~15 mN m⁻¹ in these devices. Compared to previous approaches, our transfer process features high yield and uniformity with minimal liquid and chemical exposure (only involving DI water), resulting in high-quality MoS₂ crystals and exceptional device performance and homogeneity; and our process is readily applicable to other 2D materials.

Introduction

Two-dimensional (2D) materials, derived from van der Waals crystals, such as graphene and atomic layers of transition metal dichalcogenides (TMDCs), have attracted tremendous attention due to their atomically-thin structures and distinct electronic, optical, and mechanical properties that lead to novel devices.¹⁻⁷ Suspended 2D nanostructures can play important roles, not only in characterizing physical properties (e.g., elastic modulus and thermal conductivity, etc.) of these ultrathin crystals,⁸⁻¹² but also in enhancing nanoelectronic performance through decoupling from adverse substrate effects.¹³⁻¹⁵ As such they enable novel nanomechanical systems¹⁶⁻²⁴ for promising sensor and actuator applications.

Since the successful isolation of graphene from graphite by micromechanical exfoliation,²⁵,²⁶ prototypical 2D nanomechanical devices have been fabricated mostly by exfoliation of small pieces of the layered bulk onto pre-patterned microtrenches.⁸,¹⁶,¹⁸,²⁰,²⁷⁻³² In order to integrate electrical signal transduction (e.g., for suspended field effect transistors, FETs, and resonators with electrical excitation/readout), 2D electronic devices are often released from a substrate after electron-beam lithography (EBL) followed by a sequence of metallization, wet lift-off, wet oxide (SiO₂) etch (e.g., buffered oxide etch, BOE) and critical point drying (CPD).¹³,¹⁷,²¹,³³,³⁴ Alternatively, polymer-assisted transfer techniques (e.g., utilizing polymethyl methacrylate, PMMA,⁸,¹₅,³₆ or polydimethylsiloxane, PDMS¹⁹,₂₁,₂₄,₃₇,₃₈) have been used to transfer exfoliated 2D flakes onto grooved substrates and across microtrenches (with/without pre-fabricated electrodes). However, the chemical processes involved in most of these methods have the potential of contaminating or degrading the 2D materials.

While micromechanical exfoliation faces challenges in fabricating large-scale arrays of suspended 2D crystals because of the limited flake size (typically tens of microns), this method has yielded some of the best quality and cleanest devices to date. Our approach, in contrast, utilizes CVD grown films that can be homogeneous across much larger area while, as we will describe below, exhibiting material properties competitive to, or even exceeding, that of the exfoliated films. Guided by the experience obtained on exfoliation samples, our work shows progress towards scalable fabrication of arrays of suspended 2D crystalline devices in a manner that incorporates: (i) improved yield by utilizing large area 2D materials, such as those obtained via CVD growth of atomic layers;⁹⁻¹² (ii) avoidance of material contamination, degradation and destruction associated with lithographic processing, chemical etching, polymer dissolution or decomposition, heating, etc.; (iii) compatibility with a wide set of substrate trench geometries; (iv) rapid and facile turnaround by minimal facility requirements, alignment efforts, etc.

Large-scale fabrication of suspended devices from CVD graphene has been reported earlier.³¹⁻⁴⁵ CVD graphene is usually...
We fabricate large-scale arrays of suspended MoS₂ nanomechanical resonators by employing water-assisted lift-off and PDMS-based all-dry transfer. Following CVD growth of MoS₂ from sulfur and MoO₃ precursors on 290 nm SiO₂/Si (see Methods), the growth substrate is diced into small sub-centimeter pieces with homogenous coverage of MoS₂. The substrate in Fig. 1a has a portion of the MoS₂ layer removed (violet stripe highlighted by A–A′) prior to taking the image to showcase the color contrast between the bare substrate (violet stripe) and MoS₂-covered surface. Transfer starts by gently pressing the substrate piece onto a PDMS stamp (supported from a glass slide) and locking it in place by means of Scotch tape. Subsequently, DI water droplets are injected at the perimeter of the chip (Fig. 1b). It is critical to allow water to penetrate into the SiO₂/MoS₂/PDMS interfaces while preventing the chip from sliding during lift-off: if the growth substrate and PDMS film are pressed together so firmly that water cannot wet the interface, the MoS₂ film remains on the growth substrate. Detaching the growth substrate after 1–2 min releases the MoS₂ material reliably and over a large area onto the PDMS stamp. Fig. 1c shows that the whole MoS₂ film is removed and only the violet color of the virgin substrate remains; the transferred MoS₂ film can be discerned on the PDMS stamp and the A–A′ stripe is clearly visible. Subsequent transfer onto the substrate patterned with microtrench arrays (290 nm in depth, 0.5–2 μm in diameter) proceeds without the need for any liquid solvent (Fig. 1d). Drying of the PDMS stamp with nitrogen gas prior to the final transfer step ensures that no solution trapping (suffered by some of the previously described methods) can occur and minimizes the risk of 2D crystal degradation and damage. Fig. 1e shows a fraction of the resulting array of suspended MoS₂ drumhead resonators, among the thousands obtained. The whole process is facile, rapid, and potentially applicable to a wide range of water-impervious 2D materials.

**Results and discussion**

We fabricate two types of suspended arrays by utilizing: (i) sub-centimeter size few-layer MoS₂ film and (ii) single-layer flakes

![Image of CVD MoS₂ Thin Film](Link to Image)
(~10 μm size). In each case, we have obtained extended arrays of functional nanomechanical resonators.

Fig. 2a shows an array of few-layer MoS2 drumheads (with diameters of 0.5–2 μm), which only represents a small fraction of the yield of a single transfer process. We note that the few-layer thin film (in Fig. 1c), which is orders of magnitude larger than exfoliated flakes, tore during dry transfer, forming a series of discontinuous regions of film suspended across extended arrays of substrate trenches. We attribute the tearing to mechanical deformation of the PDMS and assume that it can be avoided by further engineering of details of the transfer process. Given the large number of covered trenches (thousands) achieved in a single cycle of the current process, tearing of the MoS2 film is no obstacle to success of this experiment.

We have examined the quality of the few-layer CVD MoS2 film before and after fabrication using Raman spectroscopy (Fig. 2c).40,41,48,49 in both cases we find two sharp peaks near 380 cm$^{-1}$ and 400 cm$^{-1}$ corresponding to the 2 dominant phonon modes of the MoS2 crystal, i.e., E$_{2g}^{1}$ and A$_{1g}$. The absence of any change in linewidth of the modes in the course of the transfer process ascertains the benign nature of our procedure.

For statistical evaluation of the homogeneity of the MoS2 few-layer film suspended across the microtrenches, we measure Raman characteristics on 47 drumheads (d = 1.68 μm) as shown in Fig. 2d–g. The E$_{2g}^{1}$ and A$_{1g}$ positions and linewidths are extracted by Lorentzian fitting from each spectrum (Fig. 2d and f) and their variations are fitted to normal distributions (Fig. 2e and g). We obtain E$_{2g}^{1}$ and A$_{1g}$ position distributions of 384.3 ± 0.3 cm$^{-1}$ and 406.7 ± 0.1 cm$^{-1}$ as well as linewidth distributions of 6.4 ± 0.7 cm$^{-1}$ and 5.5 ± 0.3 cm$^{-1}$. The separation of E$_{2g}^{1}$ and A$_{1g}$ peaks,40,41,49 together with the AFM height profile (inset in Fig. 2b) and optical contrast between MoS2 and growth substrate40,50 (in Fig. 2b) indicates a trilayer film. The standard deviations are smaller than the nominal resolution of the Raman system of ∼1 cm$^{-1}$. They confirm uniform high quality of CVD MoS2 film across the entire device regions after fabrication.

As shown in Fig. 3d, our growth substrate contains a sparse distribution of single-layer MoS2 islands only (AFM height profile also determines single layer40). Our transfer technique is capable of picking up these islands quantitatively, as evidenced by the similar MoS2 island densities on the growth substrate and the PDMS stamp shown in Fig. 3d and e. Dry-transfer onto circular microtrench arrays produces large amount of suspended single-layer MoS2 drumheads (Fig. 3a), with single-layer flakes covering individual or multiple trenches (Fig. 3b and c). The overall yield of this process is determined by the density of single-layer islands on the growth substrate, not by the transfer process. We examine the quality of the transferred single-layer MoS2 flakes using both Raman and photoluminescence (PL) spectroscopy.7,40–42,48 The sharp E$_{2g}^{1}$ and A$_{1g}$ peaks in the Raman spectra (Fig. 3f) and the strong A and B exciton peaks in the PL spectra (Fig. 3g) measured before and after the transfer process indicate well-preserved crystal quality. Proceeding in the same fashion as for the few-layer films (Fig. 2), we calculate E$_{2g}^{1}$ and A$_{1g}$ position and linewidth distributions of 385.8 ± 0.3 cm$^{-1}$, 405.6 ± 0.5 cm$^{-1}$, as well as 2.9 ± 0.8 cm$^{-1}$, 4.4 ± 0.6 cm$^{-1}$, respectively, for 22 single-layer (d = 0.92 μm) drumheads. These measurements confirm the high and uniform quality of our single-layer devices.
Depending on the morphology of the MoS$_2$ films on the growth substrate, thousands of few-layer nanoresonators and hundreds of single-layer ones are prepared in a single fabrication cycle. This can still be enhanced by optimizing microtrench density and synthesizing/transferring larger, continuous single-layer films.

In the following, we validate that our MoS$_2$ drumheads can readily function as resonators, and further analyze their resonant performance statistically. We characterize their fundamental-mode nanomechanical resonances using a custom-built optical interferometry system, in which an amplitude-modulated 405 nm diode laser is employed to opto-thermally excite the out-of-plane vibrations of the suspended MoS$_2$ resonators, while a 633 nm He–Ne laser is focused on the devices to read out their mechanical vibrations. This optical interferometry system can achieve displacement sensitivities down to $10^{-12}$ m/$\sqrt{\text{Hz}}$ levels for nanomechanical resonators constructed out of various crystalline materials.$^{18,21}$

We characterize a total of 93 few-layer devices (35, 18, 16, and 24 each for diameters of 1.68, 1.16, 0.92 and 0.64 $\mu$m, respectively, as shown in Fig. 4a) and 24 single-layer devices (3, 5, 10, and 6 each for diameters of 1.68, 1.16, 0.92 and 0.64 $\mu$m, respectively, as shown in Fig. 4b). All these devices are fully-covered drumheads in few- or single-layer films. The resonance spectra are fitted to a damped simple harmonic resonator model so as to extract the resonance frequency ($f_0$) and quality ($Q$) factor for each device. The $f_0$ vs. $Q$ scatter plots are shown in the upper panels in Fig. 4a and 4b, and the statistics of $f_0$ and $Q$ are plotted in the lower panels. We observe an increase of the resonance frequency $f_0$ as the drumhead diameter $d$ decreases. For few-layer devices the values are $f_0 = 61.99 \pm 14.87$ MHz for $d = 1.68 \mu$m, $70.64 \pm 11.11$ MHz for $d = 1.16 \mu$m, $86.04 \pm 32.05$ MHz for $d = 0.92 \mu$m, and $94.31 \pm 15.53$ MHz for $d = 0.64 \mu$m. For single-layer devices the values are $f_0 = 21.35 \pm 5.19$ MHz, $36.75 \pm 15.78$ MHz, $69.88 \pm 14.61$ MHz, and $81.37 \pm 16.78$ MHz, respectively, for the same sequence of drumhead diameters. The fundamental-mode resonances of our >100 measured few- and single-layer resonators reach up to $\sim 120$ MHz, i.e., into the very high frequency (VHF) band. The device with the highest figure-of-merit is marked by a green symbol in each of the graphs of Fig. 4; the highest figure-of-merit $f_0 \times Q$ obtained is $3 \times 10^{10}$ Hz, on par or better than previously reported values for individually-prepared MoS$_2$ drumheads from mechanical exfoliation.$^{18-20}$

![Fig. 3](https://www.nanoscale.org/content/8/12/10680/F1.large.jpg) Single-layer MoS$_2$ nanomechanical resonator arrays. (a) Micrograph of region containing many MoS$_2$ nanoresonators on circular microtrenches. (b) and (c) SEM images of single-layer flakes covering single and multiple circular microtrenches, respectively. (d) and (e) sparse distribution of single-layer CVD MoS$_2$ flakes on the growth substrate and quantitative transfer onto the PDMS stamp. Inset: AFM step height profile showing the thickness of a single-layer MoS$_2$ flake (measured $\sim 0.9$ nm-thick, measurement position marked by red line). (f) Raman and (g) photoluminescence (PL) spectra of single-layer MoS$_2$ crystals on the growth substrates and suspended over microtrenches ($E_{2g}^1$ and $A_{1g}$ peaks are clearly observed in (f), and A and B peaks are observed in (g)). (h)–(k) Statistics of Raman characteristics (peak positions and linewidths) of 22 ($d = 0.92 \mu$m) single-layer MoS$_2$ drumheads.
We now discuss the dispersion of the fundamental-mode resonances in Fig. 4. Fig. 5 compares the measured $f_0$ and $Q$ dispersions of our dataset (magenta and red) to previously reported values of exfoliated MoS$_2$ resonators (violet and blue)$^{19}$ and CVD graphene resonator arrays (green).$^{43}$ We normalize the data points $X_i$ by plotting their variations from the mean $\bar{X}$ as a fraction of the mean value, i.e., $(X_i - \bar{X})/\bar{X}$. Dashed lines indicate Gaussian distributions fitted to the datasets. Herein, the box symbols illustrate the dispersions, with the top and bottom of the boxes showing the dispersion percentages (i.e., $\pm\sigma\langle X \rangle/\langle X \rangle$), and the whiskers representing the data ranges. We observe the improved $f_0$ dispersion, as low as 20.9% and 15.7% for single- and few-layer CVD MoS$_2$ resonators, in comparison to 34.1% and 22.7%, respectively, for exfoliated MoS$_2$ devices$^{19}$ and 35.8% for CVD graphene devices.$^{43}$ As for $Q$, even though we measure slightly larger dispersion in our few-

---

**Fig. 4**  Statistics of fundamental-mode resonance characteristics. (a) and (b) depict data for few- and single-layer MoS$_2$ nanomechanical resonator arrays, respectively. Within (a) and (b), the upper panels show scatter plots of the fundamental-mode resonance frequency ($f_0$) vs. the quality ($Q$) factor for devices with 4 different diameters ($d = 1.68, 1.16, 0.92, 0.64$ μm). Green symbols highlight the devices with the highest figures-of-merit $f_0 \times Q$ in each graph. The insets show the resonance spectra corresponding to the green symbols as fitted to the finite-$Q$ simple harmonic resonator model (red dashed lines). The lower panels show statistics on the distributions of $f_0$ and $Q$, respectively.

---

**Fig. 5**  Comparison of (a) fundamental-mode resonance frequency ($f_0$) and (b) quality ($Q$) factor dispersions with published work.$^{19,43}$ The CVD MoS$_2$ nanoresonator arrays in this work are shown in magenta for single-layer and red for few-layer devices; previously reported exfoliated MoS$_2$ resonators are shown in violet for single-layer and in blue for multilayer;$^{19}$ large-scale CVD graphene resonator arrays are shown in green.$^{43}$ Both our data and the reference data are normalized as described in the text.
layer CVD MoS_2 devices than in the exfoliated ones, our single-layer CVD drumheads feature an unprecedented low dispersion down to 44.3% in contrast to the 79.2% for the exfoliated MoS_2 devices and 57.9% for the CVD graphene devices. We attribute the improved statistical metrics of our devices to the facile and clean transfer process that maintains high and uniform crystal quality.

We also note that because nanomechanical resonances are much more sensitive (than, for instance, Raman spectra) to variations in the stiffness and effective mass of the suspended devices (e.g., very small variations in the pre-tension levels that are invisible in Raman measurement can affect the resonance frequency $f_0$ quite pronouncedly), there are noticeable distributions in $f_0$ and $Q$ values (in Fig. 4), while there is no appreciable non-uniform Raman peak position and FWHM (in Fig. 2 and 3).

Information on the pre-tension levels of our 2D MoS_2 drumheads can be obtained by fitting the data to a resonance frequency model of a fully-clamped stretched circular diaphragm:

$$f_0 = \frac{\rho \pi}{2\pi} \sqrt{\frac{16D}{\rho d^2}} \left[ \frac{(kd/2)^2 + \rho d^2}{4D} \right]. \quad (1)$$

where $\rho$ is the areal mass density of MoS_2, $\gamma$ the pre-tension level (N m$^{-1}$), $D$ the bending rigidity $D = E_t t/[12(1 - \nu^2)]$, with $E_t$, $\nu$ and $t$ being the Young’s modulus, Poisson’s ratio and thickness of MoS_2. Here the mode parameter is determined by $(kd/2)^2 = \alpha + (\beta - \alpha)e^{-\eta d^2/(4\delta)}$, with $\alpha = \gamma d^2/4D$, $\beta = 10.215$, $\eta = 0.1148$ and $\delta = 0.4868$, respectively.\footnote{Fig. 6b shows the results for the $d = 0.64$ μm device family. The fitting leads to an averaged pre-tension level $\gamma \approx 13$ mN m$^{-1}$ and Young’s modulus $E_t \approx 0.34$ TPa (solid dark blue line in Fig. 6b).}

Fitting the experimental results of the $f_0$ spread of single-layer drumheads in Fig. 4 (symbols and whiskers highlighting the mean and standard deviation) to eqn (1), we obtain a best overall fit for $\gamma \approx 15$ mN m$^{-1}$; the entire spread of the $f_0$ distribution corresponds to a pre-tension range of $\gamma \approx 3$–36 mN m$^{-1}$ (Fig. 6a). Assuming that our transfer method introduces similar pre-tension levels $\gamma$ to both single- and few-layer drumheads of the same diameter, we estimate $\gamma$ and $E_t$ variances. Fig. 6b shows the results for the $d = 0.64$ μm device family. The fitting leads to an averaged pre-tension level $\gamma \approx 13$ mN m$^{-1}$ and Young’s modulus $E_t \approx 0.34$ TPa (solid dark blue line in Fig. 6b). The $f_0$ dispersions are consistent with $\gamma$ in a range of 7–25 mN m$^{-1}$ and $E_t$ in a range of 0.28–0.40 TPa (violet and blue dashed lines) in our samples. The extracted $E_t$ values are in good agreement with those in previous work.\footnote{Interestingly, from the modeling we obtain much lower pre-tension levels than those reported in exfoliated/CVD MoS_2/graphene resonators.\textsuperscript{8,10,52–54} Lower pre-tension levels may be desirable in certain situations where excellent homogeneity and wide tuning ranges are required. This may be interpreted as another advantage of the water-assisted release and the dry transfer method employed in the present work.}

**Conclusion**

We have demonstrated fabrication of large arrays of suspended MoS_2 nanomechanical resonators by means of a combination of water-assisted lift-off and all-dry transfer. Our clean and
efficient process releases large areas of 2D crystals from their growth substrate while only requiring DI water. This avoids the need for chemical treatment of the 2D materials and mitigates their degradation. Results from more than 100 single- and few-layer MoS$_2$ drumhead nanoresonators show fundamental resonances in the VHF band with figure-of-merit as high as $f_0 \times Q \approx 3 \times 10^{10}$ Hz. We observe higher uniformity of the frequency and quality factor, as well as lower pre-tension levels, compared to previous results. The facile nature and the absence of any solvents but DI water in our transfer technique holds promises for enabling suspended 2D devices and arrays using other 2D materials and their heterostructures, and it is applicable to substrates with other geometries of microtrenches and electrodes.

Methods

CVD MoS$_2$ synthesis

The MoS$_2$ material was synthesized via CVD utilizing elemental sulfur and MoO$_3$ powder as precursors. The process is described in ref. 55 and the resultant material compares well with exfoliated material. In brief, film growth proceeds by placing alumina boats containing the precursors at different positions in a quartz process tube. The growth substrate is placed directly atop the boat containing the MoO$_3$ powder. Initially, the quartz tube is inserted into a tube furnace so that the MoO$_3$ boat comes to rest at the furnace center. The furnace is gradually heated up to 680 °C while a continuous flow of N$_2$ gas transports the sulfur vapor to the growth substrate. After the furnace has reached the growth temperature, the temperature is held for a few minutes and then the furnace is cooled gradually to room temperature while the N$_2$ gas flow is maintained. This procedure results in a few-layer MoS$_2$ film where the growth substrate covers the MoO$_3$ boat; where the growth substrate overhangs the MoO$_3$ boat on the side, single-layer film and isolated single-layer flake islands are obtained. The MoS$_2$ crystals were characterized optically via Raman and photoluminescence (PL) spectroscopy before being shipped from UC Riverside to Case Western Reserve University for further Raman and PL measurements, transfer, and the following characterization of the drumheads and arrays.

Fabrication of microtrenches

Large arrays of microtrenches are lithographically defined and fabricated on 290 nm-SiO$_2$-on-Si substrate. The SiO$_2$ layer is patterned with microtrenches using photolithography, and then etched by reactive ion etching (RIE). The depth of resulting SiO$_2$ microtrenches is 290 nm in this experiment, and the nominal values for the diameters in the design are 1.5, 1, 0.75 and 0.5 μm (corresponding to 1.68, 1.16, 0.92, 0.64 μm after the fabrication process).

Interferometric resonance measurement

Fundamental resonances of the resulted suspended MoS$_2$ drumhead resonators are characterized using optical excitation and detection techniques. An amplitude-modulated 405 nm blue laser is employed to opto-thermally excite the flexural vibrations of the suspended MoS$_2$ nanoresonator, while a 633 nm He–Ne laser is focused on the device surface for detection of the motion-modulated interference between multiple reflections from the flake–vacuum, vacuum–SiO$_2$ and SiO$_2$–Si interfaces, which is read out by a low-noise photodetector. A network analyzer is used to modulate the blue laser as well as measure the response from the photodetector. We apply a blue laser power of ~39 μW and red laser power of ~1.23 mW to the devices which are preserved under moderate vacuum conditions (~90 mTorr) to ensure reasonable signal-to-noise ratio while avoiding laser degradation and overheating.
